How long have lice been parasites of humans? Our discovery of an intact louse egg (Fig. 1) on a hair that is over 10,000 years old pushes the previously reported date back by 8,000 years, providing a new insight into the co-evolutionary history of humans and parasites.

'Louse' refers to three human parasites: head lice (Pediculus humanus), body lice, and crab lice, which inhibit head hair, clothing, and body hair, respectively. Until now, ancient texts1, mummies2 and artifacts3 have provided evidence of all three forms of ancient lice. Pediculus humanus has been found in archaeological sites in southwest USA, the Aeolian Islands, Peru4, Greenland5, Mexico6 and in mummies of Inca sacrifices7.

We discovered the louse egg while analyzing human hair from an archaeological site in northeast Brazil. This egg is not only older than previously reported louse eggs, but is also the first evidence of ancient head lice in the Americas, indicating that head lice perhaps arrived with the first human colonists that entered the New World. Radiocarbon dates for strata containing other artifacts from the site, such as stone tools, prehistoric rock art and an unassociated human skeleton, as well as the hair, were 9870 ± 50 years (Beta 109844) and 10640 ± 80 years (Beta 104571), respectively. The egg was identified as P. humanus based on morphology and size (~1 mm), and the fact that it was attached to human head hair. The short cement base visible in Fig. 1 is also compatible with that of P. humanus.

Several authors believe that lice have been associated with humans since our pre-hominid ancestors, and were dispersed throughout the world by early human migrants8-10, a hypothesis supported by our find. Other researchers noted differences between the adults of Pediculus from pre-Columbian South and North American Indians11. This suggests the evolution of different strains of lice in different parts of the world12. Direct examination of prehistoric louse geographical and temporal isolates will contribute to this discussion. Information about louse epidemiology can also come from the study of ancient lice, e.g. studies of lice from large samples of mummies from prehistoric Peru13. Revealed differences in louse infection between males and females and adults and children due to differences in hair styles and grooming14 (Box 1).

It may be that one louse species Pediculus (P. capitis) mijibergi, from New World monkeys, evolved from P. humanus through past contact between human and monkeys15. Comparative examination of the morphology or DNA of ancient lice and modern-day P. mijibergi will help establish whether this hypothesis is correct.

There is no doubt that future studies of the lice found in Brazil and of lice from other archaeological sites will contribute to the understanding of the evolutionary and natural history of the louse and its relationship with humans.

This research was funded by CNPq, FIOCRUZ, and Fundação Museu do Homem Americano.

Box 1. Prehistoric Control of Lice in the New World

As in human populations today, lice were a common problem for prehistoric cultures. Lice have been found in hunter–gatherer and agricultural sites in the USA (Great Basin of Utah and surrounding states and the Colorado Plateau) and from central Mexico8. The prehistoric peoples in these areas appeared to control the lice by eating lice groomed from hair (a common method of louse control among tribal cultures16, even today) as adult lice have been found deep in the matrix of coprolites17,18.

House style appears to have been another cultural aspect to controlling louse infection. The crowded, warm, subterranean houses of prehistoric Eskimos and Aleuts, and the development of prehistoric 'apartment-like' housing among southwestern Anasazi peoples provided ideal conditions for louse infestations (as well as pinworms19) and controlling lice depended on mutual grooming and sweat baths. By contrast, the open and nomadic habits of prehistoric Southwestern and Great Basin hunters and gatherers kept these populations relatively louse free19.
